

# Grow with the flow: a latitudinal cline in physiology is associated with more variable precipitation in *Erythranthe cardinalis*

## Abstract

Local adaptation is commonly observed in nature: organisms perform well in their natal environment, but poorly outside it. Correlations between traits and latitude, or latitudinal clines, are among the most common pieces of evidence for local adaptation, but identifying the traits under selection and the selective agents is challenging. Here, we investigated a latitudinal cline in growth and photosynthesis across 16 populations of the perennial herb *Erythranthe cardinalis* (Phrymaceae). Using machine learning methods, we identify interannual variation in precipitation as a likely selective agent: Southern populations from more variable environments had higher photosynthetic rates and grew faster. We hypothesize that selection may favor a more annualized life history – grow now rather than save for next year – in environments where severe droughts occur more often. Thus our study provides insight into how species may adapt if Mediterranean climates become more variable due to climate change.

## Introduction

1 Local adaptation has been documented within numerous species; populations generally  
2 have higher fitness in their native environment, but perform poorly outside it (Schluter,  
3 2000; Leimu and Fischer, 2008; Hereford, 2009). However, the prevalence of local adapta-  
4 tion remains difficult to assess because researchers rarely test for local adaptation unless  
5 there are obvious phenotypic or environmental differences (but see Hereford and Winn  
6 2008). When local adaptation occurs, it frequently leads to clines in both phenotypes and

7 allele frequencies when selection varies over environmental gradients (Huxley, 1938; Endler,  
8 1977; Barton, 1999). Phenotypic differences between populations along a cline often have  
9 a genetic basis and can be studied in a common garden (Turesson, 1922; Clausen et al.,  
10 1940; Hiesey et al., 1942). Despite a long history of studying local adaptation and clines,  
11 it remains challenging to identify exactly which traits are under selection and which differ  
12 for nonadaptive reasons. In particular, the role that physiological differences play in local  
13 adaptation is poorly understood, despite the fact that physiology is frequently assumed to  
14 explain adaptation to the abiotic environment. A related problem is identifying which of  
15 the myriad and often covarying aspects of the environment causes spatially varying selective  
16 pressures.

17 When populations are locally adapted, reaction norms for fitness will cross, such that local  
18 genotypes have higher fitness than foreign genotypes and rank orders change across envi-  
19 ronments (Kawecki and Ebert, 2004). The traits that underlie local adaptation, however,  
20 need not mirror this pattern. Populations can have fixed genetic differences conferring  
21 trait values that are adaptive at home but neutral or maladaptive away. Alternatively,  
22 the ability to plastically respond to a particular environment or the magnitude of response  
23 to an environment could be adaptive. We distinguish between these patterns of adaptive  
24 trait differences by referring to ‘intrinsic’ and ‘plastic’ trait variation, respectively. Both  
25 intrinsic and plastic trait variation can be explained by genetic differences and both are  
26 involved in adaptation. For example, intrinsic differences in photoperiod responses (Black-  
27 man et al., 2011) and developmental rate (Stinchcombe et al., 2004) allow organisms to  
28 properly time their life history with the local environment. Conversely, sun and shade  
29 plants do not have intrinsically higher or lower rates of carbon assimilation, but rather,  
30 genotype-by-environment interactions cause sun plants to assimilate more under high light  
31 and shade plants under low light (Givnish, 1988). In plants especially, we know little about  
32 the prevalence and adaptive significance of variation in fundamental physiological traits like  
33 photosynthesis and their impact on plant performance (Flood et al., 2011).

34 A basic approach to identify candidate traits underlying local adaptation is to find asso-  
35 ciations between traits and environments. Either intrinsic and/or plastic variation should  
36 vary clinally along environmental gradients. Indeed, clines in ecologically important traits  
37 are widespread in nature (Endler, 1977) and often adaptive, but in most cases the selective  
38 agent is unknown. For example, in *Drosophila* numerous latitudinal clines exist for traits  
39 like thermal tolerance (Hoffmann et al., 2002), body size (Coyne and Beecham (1987) and  
40 references therein), and life history (Schmidt et al., 2005). Some *Drosophila* clines have  
41 evolved multiple times (Oakeshott et al. (1982); Huey et al. (2000), see also Bradshaw and  
42 Holzapfel (2001)) or shifted in response to climate change (Umina et al., 2005), evincing  
43 climatic adaptation. Similarly, plant species exhibit latitudinal clines in traits like flowering  
44 time (Stinchcombe et al., 2004), cyanogenesis (Kooyers and Olsen, 2012), leaf morphology  
45 (Hopkins et al., 2008; Stock et al., 2014), and drought response (Kooyers et al., 2015) that  
46 likely relate to climatic variation.

47 Despite the fact that latitudinal clines have been studied for a long time, latitude *per se*  
48 cannot be a selective agent. Latitude may be strongly correlated with one or two key  
49 climatic variables, such as temperature, precipitation, or growing degree-days. Latitude  
50 may also correlate with the strength of biotic interactions (Schemske et al., 2009) or other  
51 nonclimatic aspects of the environment, though as we explain below, we do not yet have  
52 compelling data that these are important in our study system. Hence, we focus on whether  
53 latitude could be an effective proxy for an underlying climatic driver, in which case we  
54 would expect a yet stronger relationship between traits and the key climatic variable(s)  
55 driving selection. Alternatively, latitude may be more strongly related to traits than any  
56 single climatic variable for at least two reasons. First, latitude may be correlated with  
57 several climatic agents of selection that are individually weak, but add up to a strong  
58 latitudinal cline. Alternatively, gene flow among neighbouring populations could smooth  
59 out local climatic effects, since alleles will experience selection across populations linked  
60 by migration (Slatkin, 1978; Paul et al., 2011; Hadfield, 2016). We refer to this as the

61 ‘climatic neighborhood’. For example, in mountainous regions average temperature at  
62 a given latitude varies widely, but in aggregate, a lower latitude set of populations will  
63 experience warmer climate than a higher latitude one. Thus, any particular low latitude  
64 population would be warm-adapted, even if it was located in a cooler (e.g. high elevation)  
65 site. Because many climatic factors vary latitudinally, and which climatic factors vary  
66 latitudinally changes over the earth’s surface (e.g. coastal vs. continental), dissecting the  
67 evolution of latitudinal clines across many species will help identify generalities, such as  
68 whether thermal tolerance maxima or seasonal timing is more important (Bradshaw and  
69 Holzapfel, 2008), and whether local or regional climate shapes selective pressures.

70 In this study, we investigated two major questions: 1) whether intrinsic or plastic physiolog-  
71 ical trait variation corresponds with latitude; and 2) what climatic factor(s) could plausibly  
72 be responsible for latitudinal clines. Within question 2, we tested three hypotheses outlined  
73 in the previous paragraph: latitudinal clines are explained by a single dominant climatic  
74 factor, multiple climatic factors, or the climatic neighborhood experienced by nearby popu-  
75 lation connected through gene flow. These hypotheses are not mutually exclusive since, for  
76 example, single or multiple factors in a climatic neighborhood may lead to latitudinal clines.  
77 We focused on climate because climate often determines where species are found and  
78 also can exert strong selection on populations within species, though we acknowledge that  
79 other abiotic and biotic factors could also contribute to selection and the overall pattern  
80 of local adaptation. There is also a compelling need to know how populations are (or are  
81 not) locally adapted to climate so as to predict how they will respond to climate change  
82 (Aitken and Whitlock, 2013).

83 We examined these questions in *Erythranthe cardinalis* (formerly *Mimulus cardinalis* [Ne-  
84 som 2014]) because linking physiological traits to potentially complex patterns of local  
85 adaptation requires integrating multiple lines of evidence from comparative, experimental,  
86 and genomic studies under both lab and field conditions. Many classic and contemporary  
87 studies of local adaptation use *Mimulus sensu lato* species because of their natural his-

88 tory, easy propagation, and genetic/genomic resources (Clausen et al., 1940; Hiesey et al.,  
89 1971; Bradshaw and Schemske, 2003; Wu et al., 2008; Lowry and Willis, 2010; Wright  
90 et al., 2013). Yet, there is a deficiency of links between local adaptation and physiological  
91 mechanisms (Angert, 2006; Angert et al., 2008; Wu et al., 2010; Wright et al., 2013). We  
92 measured genetic and genotype-by-environment variation in response to temperature and  
93 drought among 16 populations distributed over 10.7° of latitude. We found a latitudinal  
94 cline of intrinsic variation in photosynthesis and growth, but little evidence for variation in  
95 plasticity. Interannual variation in precipitation and temperature are associated with this  
96 axis of variation, suggesting that climatic variance rather than mean may be an important  
97 driver of local adaptation in *E. cardinalis*. The climatic neighborhoods around populations  
98 explained trait variation better than local climate, indicating that latitudinal clines may be  
99 common because latitude integrates effects of selection on populations connected through  
100 gene flow. We place these findings in the context of life history theory and consider future  
101 directions in the Discussion.

## 102 **Material and Methods**

### 103 **Population Selection**

104 *E. cardinalis* is a perennial forb native to the Western US (California and Oregon). It is  
105 predominantly outcrossing, self-compatible, and pollinated primarily by hummingbirds.  
106 We used 16 populations from throughout the range of *E. cardinalis* (Table 1). These  
107 populations were intentionally chosen to span much of the climatic range of the species  
108 based on all known occurrences (see below). Seeds were collected in the field from mature,  
109 undehisced fruit left open for 2-4 weeks to dry, then stored at room temperature. We used  
110 seeds from 154 families, 4-12 (mean = 9.6, median = 12) families per population.

**Table 1:** Latitude, longitude, and elevation (mas = meters above seal level) of 16 focal populations used in this study.

Name	Latitude	Longtiude	Elevation (mas)
Hauser Creek	32.657	-116.532	799
Cottonwood Creek	32.609	-116.7	267
Sweetwater River	32.9	-116.585	1180
Grade Road Palomar	33.314	-116.871	1577
Whitewater Canyon	33.994	-116.665	705

Rock Creek	43.374	-122.957	326

## Plant propagation

On 14 April, 2014, 3-5 seeds per family were sown directly on sand (Quikrete Play Sand, Georgia, USA) watered to field capacity in RLC4 Ray Leach cone-tainers placed in RL98 98-well trays (Stuewe & Sons, Inc., Oregon, USA). We used pure sand because *E. cardinalis* typically grows in sandy, riparian soils (A. Angert, pers. obs.). Two jumbo-sized cotton balls at the bottom of cone-tainers prevented sand from washing out. Cone-tainers sat in medium-sized flow trays (FLOWTMD, Stuewe & Sons, Inc., Oregon, USA) to continuously bottom-water plants during germination in greenhouses at the University British Columbia campus in Vancouver, Canada (49°15' N, 123°15' W). Mistlers thoroughly wetted the top of the sand every two hours during the day. Most seeds germinated between 1 and 2 weeks, but we allowed 3 weeks before transferring seedlings to growth chambers. We recorded germination daily between one to two weeks after sowing, and every 2-3 days thereafter.

On 5 May (21 days after sowing), we transferred seedlings to one of two growth chambers (Model E-15 Conviron, Manitoba, Canada). We thinned seedlings to one plant per container, leaving the center-most plant. 702 of 768 (91.4%) had plants that could be used in the experiment. We allowed one week at constant, non stressful conditions (day: 20°C, night: 16°C) for plants to acclimate to growth chambers before starting treatments. The initial size of seedlings, measured as the length of the first true leaves, did not differ between populations, families, or treatments (Table S1).

## Temperature and drought treatments

We imposed four treatments, a fully-factorial cross of two temperature levels and two watering levels. The temperature levels closely simulated an average growing season at the thermal extremes of the species range, which we designate as Hot and Cool treatments. Watering levels contrasted a perennial and seasonal stream, which we refer to as Well-watered and Drought treatments. A detailed description of treatments is provided in the Supplemental Materials and Methods and summarized in Fig 1. Because growth chambers cannot be subdivided, one chamber was assigned to the Hot treatment level and another to the Cool treatment level. Within each chamber, there were two Well-watered blocks and two Drought blocks. The photosynthetically active radiation in both chambers was approximately  $400 \mu\text{mol quanta m}^{-2} \text{ s}^{-1}$  and set to a 16:8 light:dark cycle to simulate summer growing conditions. The growth chambers did not control humidity, but because of watering and high plant transpiration rates, the relative humidity was quite high in both temperature levels (data not shown). Lower humidity would have made the drought more severe, but low soil moisture is stressful in and of itself. The total number of plants in each treatment was:  $n_{\text{cool,dry}} = 169$ ;  $n_{\text{cool,ww}} = 174$ ;  $n_{\text{hot,dry}} = 176$ ;  $n_{\text{hot,ww}} = 183$ . Each population had 8–12 individuals per treatment level (mean = 11, median = 11).

**Figure 1:** Overview of experimental treatments and timing of key trait measurements. All plants germinated within 21 days of sowing. At that time, we began temperature treatments (left axis), simulating a typical June–August weather pattern at Hot (red) and Cool (blue) sites. The bold lines track the average daily temperatures. Within each day, there was a maximum daytime temperature (top of translucent polygons) and minimum nighttime temperature (bottom of translucent polygons). The drought treatment commenced later by ramping down the frequency of bottom-watering episodes (dashed black line; right axis), while watering frequency was maintained in the control treatment (solid black line). Grey boxes on the bottom of the plot outline the period of key measurements described in the Material and Methods.

## Trait measurements

We measured five traits in response to temperature and watering treatments (Table 2).

**Days to germination** We tested for population variation in germination rate, measured as Days to Germination, using a lognormal survival model fit using the `survreg` function in the R package **survival** version 2.38 (Therneau, 2015). We treated Population as a fixed effect and Family as random effect using a  $\Gamma$  frailty function. Statistical significance of the

**Table 2:** Key traits measured in this study.

Trait	Units
Days to germination	day
Leaf expansion rate	mm day <sup>-1</sup>
Stem elongation rate	cm day <sup>-1</sup>
Photosynthetic rate	$\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$
Mortality	probability of death

Population effect was determined using analysis of deviance. Note that, unlike other traits discussed below, we did not include Block, Treatment, or Population  $\times$  Treatment interactions because during germination plants had not been placed into blocks and treatments had not yet been applied.

**Growth rate: leaf expansion and stem elongation** We measured growth rate during two phases: leaf expansion and stem elongation. Growth measurements were taken during the early vegetative stage. We censused leaf length twice per week shortly after the emergence of true leaves from 12 May – 12 June (28–59 days after sowing), resulting in 10 measurements. We ceased measuring leaf length once it appeared to asymptote and growth shifted to stem elongation. We also censused plant height on 7 occasions (twice per week) between 29 May and 20 June (45 to 67 days after sowing) until plants began to initiate floral buds. Thus all growth measurements occurred during the vegetative, pre-reproductive phase. Both leaf expansion and stem elongation were modelled separately as second-order polynomials. We used empirical Bayes’ estimates of growth for each individual plant from linear mixed-effects models fit with the R package **lme4** version 1.1-12 (Bates et al., 2015).

**Photosynthesis** During the week of 10 to 16 June (57 to 63 days after sowing), we measured daytime photosynthetic rate on a subset of 329 plants evenly spread between

171 treatments and families within populations. The youngest, fully-expanded leaf acclimated  
 172 for 3 minutes to reach steady state in a 6-cm<sup>2</sup> chamber of a LI-COR 6400XT Portable Pho-  
 173 tosynthesis System (LI-COR Biosciences, Lincoln, Nebraska). We made all measurements  
 174 at ambient light (400  $\mu\text{mol m}^{-2} \text{ s}^{-1}$  of photosynthetically active radiation), atmospheric  
 175 CO<sub>2</sub> (400 ppm), temperature, and moderate relative humidity. During this period, we sus-  
 176 pended normal day-to-day temperature fluctuations and set daytime temperatures to the  
 177 average for that period (Cool: 26.5°; Hot: 36.1°) so that all plants within a temperature  
 178 level could be measured under the same conditions.

179 **Mortality** We assayed mortality during twice-weekly growth measurements. We ana-  
 180 lyzed the probability of surviving until the end of the experiment as a function of popula-  
 181 tion, treatment, and their interactions using a Generalized Linear Mixed Model (GLMM)  
 182 assuming binomially distributed errors. We included Family and Block as random effects.  
 183 We assessed significance of fixed effects using Type-II Analysis of Deviance with Wald  $\chi^2$   
 184 tests in the R package **car** (Fox and Weisberg, 2011).

## 185 **Intrinsic variation and plasticity**

186 For all traits (Table 2) except germination (see above), we tested for Population, Treat-  
 187 ment (Temperature, Water, and Temperature  $\times$  Water), and Population  $\times$  Treatment  
 188 interactions (Population  $\times$  Temperature, Population  $\times$  Water, and Population  $\times$  Temper-  
 189 ature  $\times$  Water). We interpreted significant Population effects to indicate intrinsic variation  
 190 and Population  $\times$  Treatment interactions to indicate variation in plasticity. As mentioned  
 191 above, we used survival and GLMM models for germination rate and mortality, respec-  
 192 tively. For all other traits, we used mixed model ANOVAs with Family and Block included  
 193 as random factors. We fit models using restricted maximum likelihood in **lmer**, a function  
 194 in the R package **lme4** (Bates et al., 2015). We determined significant fixed effect terms us-

ing a step-wise backward elimination procedure implemented with the step function in the R package **lmerTest** version 2.0-32 (Kuznetsova et al., 2016). This package uses Satterthwaite’s approximation to calculate denominator degrees of freedom for  $F$ -tests. We also included days to germination as a covariate in growth analyses. To ensure that Population and Treatment effects were specific to a particular growth phase, we included germination day as a covariate in leaf expansion and stem elongation analyses.

## Principal components of germination, growth, and photosynthesis

For each single-trait model above, we extracted the Population coefficient (factoring out Treatment and other effects). The multivariate distribution of these coefficients was then summarized using principal components analysis. The first principal component of these traits (TraitPC1) loaded positively with germination, growth, and photosynthetic rate, therefore we define this as a phenotypic axis delineating fast to slow growth.

## Identifying putative selective agents

Latitudinal clines are common, but it is often difficult to ascribe this variation to a particular selective agent. To reiterate, we tested three non-mutually exclusive hypotheses about how such latitudinal clines emerge: 1) one or two climatic variables explain latitudinal trait variation; 2) latitude is a proxy for multiple climatic factors that together shape trait variation; and 3) latitude integrates selection in a broader climatic neighborhood. We found that a population’s position along TraitPC1 correlated strongly with the latitude of origin (see Results) and next used Random Forest regression (Liaw and Wiener, 2002) to identify putative climatic factors underlying trait-latitude associations in *E. cardinalis*. We reasoned that if we identified a single climatic factor that explained more trait variation than latitude, then this would suggest that factor is a key selective agent underlying the latitudinal cline (Hypothesis 1). On the other hand, if multiple climatic factors together

219 are necessary to explain trait variation, then this would suggest that many climatic factors  
 220 together have imposed selection for the latitudinal cline (Hypothesis 2). We hereafter refer  
 221 to factors identified in this analysis as ‘Climate-TraitPC1’ variables. To test Hypothesis  
 222 3 about climatic neighborhoods driving selection, we directly compared local with neigh-  
 223 borhood climate. We used the immediate collection location for local climate. For climate  
 224 neighborhoods, we sampled climate at 1000 random points (at 90-m resolution) within a  
 225 62-km radius buffer around the collection and took the average. We chose this buffer radius  
 226 based on population genetic structure, as inferred from  $\approx 25,000$  restriction-site associated  
 227 SNPs among 49 populations from across the range (Paul et al., In review). Spatial auto-  
 228 correlation in allele frequencies persists for 62 km. However radii of 10 km<sup>2</sup> and 100 km<sup>2</sup>  
 229 resulted in similar outcomes (data not shown). Since *E. cardinalis* is found exclusively in  
 230 riparian areas, we only selected points along streams using the National Hydrography  
 231 Dataset (United States Geological Survey, 2015). Climatic means and variances (see below)  
 232 were weighted by their climatic suitability as determined using a multimodel ensemble av-  
 233 erage of ecological niche models (Angert et al., 2016). In addition to comparing local and  
 234 neighborhood climate, we compared the univariate correlation between local and neigh-  
 235 borhood climate with TraitPC1 and Latitude using paired *t*-tests. We adjusted degrees  
 236 of freedom to account for the fact that many climatic factors are highly correlated and  
 237 not independent. Specifically, we calculated the effective number of independent climatic  
 238 factors ( $M_{\text{eff}}$ ) using the formula  $M_{\text{eff}} = 1 + (M - 1)(1 - \text{Var}(\lambda)/M)$  (Chevrud, 2001), where  
 239  $M$  is the original number of climatic factors and  $\lambda$  are the eigenvalues of the correlation  
 240 matrix of all climatic factors.

241 To help eliminate potentially spurious correlations between TraitPC1 and climate, we tested  
 242 for overlap between climatic variables that best predict latitude of all *E. cardinalis* occur-  
 243 rence records (see detail below), not just the 16 focal populations. We refer to these climatic  
 244 factors as ‘Climate-Latitude’ variables. The logic is that climatic factors associated with  
 245 both TraitPC1 and latitude for all populations are more likely to be important selective

agents than climatic factors that happen to correlate with TraitPC1 but do not covary with latitude throughout the *E. cardinalis* range. Therefore, we did not consider Climate-TraitPC1 variables to be candidate selective agents unless the same or very similar variable was found in the Climate-Latitude analysis. However, we do interpret potential selective agents identified in Climate-Latitude analyses alone, because the goal was to explain the latitudinal clines in traits, not all aspects of climate that vary with latitude.

We selected Climate-Latitude and Climate-TraitPC1 variables independently using Variable Selection Using Random Forest (VSURF) algorithm in the R package **VSURF** version 1.0.3 (Genuer et al., 2016). Random Forest regression is useful for cases like ours when the number of potential predictors is similar to or greater than the number of observations ('high  $p$ , low  $n$ ' problem). VSURF is a multistep algorithm that progressively retains or eliminates variables based on their importance over regression trees in the forest. Variable importance is defined as the average amount a climate variable reduces mean-squared error in the predicted response (TraitPC1 or Latitude), compared to a randomly permuted dataset, across all trees in the random forest (see Genuer et al. [2015] for further detail). Hence, VSURF automatically eliminates unimportant and redundant variables based on the data without having to arbitrarily choose among colinear climate variables before the analysis. We kept only variables selected for prediction, the most stringent criterion. A visual overview of how we selected climatic variables is depicted in Fig 2.

For Climate-Latitude analyses, we compiled a representative set of 356 recent (since 2000) known *E. cardinalis* occurrences from a comprehensive set of herbarium records and an exhaustive field survey in 2010-11 (Angert et al., 2016). These occurrences were thinned by 50% to correct for uneven sampling. For both Climate-TraitPC1 analyses (16 focal populations) and Climate-Latitude (many populations), we used a 90-m digital elevation model from HydroSHEDS (Lehner et al., 2006) to extract elevation. Monthly interpolated climate layers were calculated using ClimateWNA version 5.30 (Wang et al., 2012), which accurately downscales climate data specifically for the rugged topography of western North

273 America. For each occurrence, we calculated bioclimatic variables using the biovars function  
 274 in the R package **dismo** version 1.1-1 (Hijmans et al., 2016). We included 24 climatic  
 275 factors, 9 from ClimateWNA and 15 bioclimatic variables (Table S2). The bioclimatic  
 276 variables included all permutations of two climatic factors, temperature and precipitation,  
 277 and six temporal scales (annual average, coldest quarter, warmest quarter, wettest quarter,  
 278 driest quarter, or seasonality) as well as mean diurnal range, isothermality, and annual  
 279 temperature range. For each variable, we calculated both a 30-year normal by averaging  
 280 annual values between 1981 and 2010 and 30-year coefficient of variation, a standardized  
 281 metric of interannual climatic variation. Temperatures were converted to Kelvin to be  
 282 on a ratio scale appropriate for calculating the coefficient of variation (CV). In total, the  
 283 VSURF algorithm selected among 96 climate variables: 24 climatic factors  $\times$  2 types (30-  
 284 year average and CV)  $\times$  2 spatial scales (local and neighborhood).

## 285 Results

### 286 A coordinated latitudinal cline in germination, growth, and photosynthe- 287 sis

288 There are strong genetically-based trait differences in time to germination, growth, and  
 289 photosynthetic rate among populations of *E. cardinalis*, as evidenced by large and signif-  
 290 icant population effects for these traits (Table 3). A single principal component captured  
 291 71.6 % of the trait variation among populations, defining an axis of variation from fast to  
 292 slow growth. A population's position along this axis strongly covaried with its latitude of  
 293 origin; southern populations grew faster than northern populations (Fig 3). There were  
 294 similar latitudinal clines for individual traits underlying PC1 (Figures S1 to S4).

**Table 3:** Summary of Population, Treatment, and Population  $\times$  Treatment effects. We used different statistical modeling for the diverse traits assayed – glmer: generalized linear mixed model using the R package **lme4** (Bates et al., 2015); lmer: linear mixed model using the R package **lme4** (Bates et al., 2015); survreg: survival regression using the R package **survival** (Therneau, 2015). Note that temperature and water treatments were imposed after germination, hence are not applicable to this trait. Complete analysis of variance/deviance tables for each trait are available in the Supporting Information. Key to statistical significance: \* $P < 0.05$ ; \*\*  $P < 0.01$ ; \*\*\*  $P < 0.001$

### Little evidence for variation in plasticity

Genotype  $\times$  environment (G $\times$ E) interactions are also a common signature of local adaptation. In contrast to the intrinsic differences described above, we found little evidence of G $\times$ E in *E. cardinalis*. There were only two statistically significant Population  $\times$  Treatment interactions (Table 3, Fig. S5), but these were not strong compared to Population and Temperature effects. Otherwise, populations responded similarly to treatments: faster growth in the hot treatment, slower growth in the dry treatment, and high mortality in the hot, dry treatment (Table 3). Complete ANOVA tables are available in the Supporting Information (Tables S3 to S6)

### Neighborhood climatic variability best explains latitudinal cline

Interannual variation in climate averaged over each populations's climatic neighborhood correlated most strongly with trait variation and latitude of *E. cardinalis* occurrences

(Fig. 4, Table S7). All 16 Climate-Latitude and 3 Climate-TraitPC1 variables were neighborhood rather than local variables (Fig. 4). In fact, neighborhood climate almost always correlated better with TraitPC1 and Latitude than local climate (Fig. 5). On average, neighborhood Climate-TraitPC1 correlation coefficients were 0.16 higher than correlations with local-scale climate variables (paired  $t$ -test,  $t = 7.87$ , d.f. = 33.6,  $P = 3.94 \times 10^{-9}$ ). Likewise, neighborhood Climate-Latitude correlation coefficients were 0.13 higher than those for local-scale climate (paired  $t$ -test,  $t = 6.71$ , d.f. = 36.8,  $P = 7.22 \times 10^{-8}$ ).

Among Climate-Latitude and Climate-TraitPC1 variables, neighborhood climatic variability over 30 years (1981–2010) in either winter precipitation (bio16 $_{\sigma}$ ) and/or temperature (bio11 $_{\sigma}$ ) are the strongest candidates to explain the latitudinal cline in *E. cardinalis* (see Table S2 for a key to climate variable abbreviations). Note that the coefficient of variation of a climatic factor is subscripted with  $\sigma$  whereas the mean is subscripted with  $\mu$ . More specifically, greater winter precipitation variability and lower winter temperature variability are associated with Southern latitudes and higher TraitPC1 values (Fig. 6A,B). Neighborhood interannual variation in winter precipitation (bio16 $_{\sigma}$ ) was the most important Climate-Latitude variable (Fig. 4A). However, neighborhood bio16 $_{\sigma}$  did not overlap with Climate-TraitPC1 variables (Fig. 4B). We nevertheless consider it a plausible candidate for two reasons. First, neighborhood bio16 $_{\sigma}$  correlated strongly with TraitPC1 (Fig. 6A). Second, one of the most important Climate-TraitPC1 variables (neighborhood bio15 $_{\sigma}$ ; Fig. 6B,C) is very similar to bio16 $_{\sigma}$ . In Mediterranean climates like California, most precipitation occurs in the wettest quarter (winter), so years with low winter precipitation also have low precipitation seasonality. Hence, highly variable year-to-year winter precipitation at lower latitude (Fig. 6D) is closely associated with large swings in precipitation seasonality (Fig. 6C).

Interannual variation in temperature of the coldest quarter (neighborhood bio11 $_{\sigma}$ ) is another plausible candidate because it was the only variable in both Climate-Latitude and Climate-TraitPC1 analyses (Fig. 4). Neighborhood bio11 $_{\sigma}$  explained more variation in

334 TraitPC1 than latitude (latitude  $r^2 = 0.55$  vs. bio11 $_{\sigma}$   $r^2 = 0.6$ ; Fig. S6), whereas neigh-  
 335 borhood bio16 $_{\sigma}$  did slightly worse (bio16 $_{\sigma}$   $r^2 = 0.49$ ). Models using bio15 $_{\sigma}$  or bio11 $_{\sigma}$  to  
 336 predict TraitPC1 also had significantly lower Akaike Information Criteria (AIC) than the  
 337 latitude model (AIC of different models – bio15 $_{\sigma}$ : 48.5; bio11 $_{\sigma}$ : 52.4; latitude: 54.5). The  
 338 best two-factor model including both neighborhood bio15 $_{\sigma}$  and bio11 $_{\sigma}$  did not significantly  
 339 improve explanatory power ( $r^2 = 0.71$ , AIC= 49.2). In summary, either variation in precip-  
 340 itation or temperature seasonality may be important selective agents, but there is no strong  
 341 evidence that they are both important. The most important Climate-TraitPC1 variable,  
 342 neighborhood variation in mean diurnal range (bio2 $_{\sigma}$ ; Fig. 4B) did not have any obvious  
 343 similarity to Climate-Latitude variables. Given the large number of potential associations,  
 344 we therefore think this may be a spuriously strong relationship.

## 345 Discussion

346 We found evidence for one of two common signatures of local adaptation in the perennial  
 347 herb *Erythranthe cardinalis*. Latitudinal clines in germination rate, photosynthesis, and  
 348 growth suggest adaptive differentiation in important physiological traits of the species.  
 349 However, we found little evidence that populations respond differently to temperature or  
 350 drought. Due to low replication within families, we did not have power to assess within-  
 351 population genotype-by-environment interactions, which may be present. As we discuss  
 352 below, low variation in plasticity among populations may indicate that some dimensions  
 353 of the fundamental abiotic niche are relatively conserved. Note that statistical power to  
 354 detect significant plasticity is lower than that for intrinsic differences. However, the fact  
 355 that the Population and Temperature effects were often highly significant ( $P \ll 0.001$  in  
 356 most cases) suggests that statistical power alone cannot explain low variation in plasticity.  
 357 Finally, our results suggest that neighborhood-scale climate and interannual variation are  
 358 more important selective agents than local averages. In the paragraphs that follow, we tie

these results into the broader threads of evolutionary theory that might help explain why intrinsic variation in physiology changes clinally, whereas plastic responses to temperature and drought are relatively static. One caveat to bear in mind is that we are limited by the size of the climate grid ( $\approx 90 \text{ m}^2$ ) and therefore unable to detect very fine-scale local adaptation.

Evolutionary theory indicates that the shape of fitness tradeoffs, demography, and gene flow can constrain adaptation (Levins, 1968; Ronce and Kirkpatrick, 2001; Lenormand, 2002) and hence the type of variation maintained within species. Specifically, adaptive variation can be maintained by spatially varying selection if tradeoffs are not too strong, demography is symmetric, and/or maladaptive gene flow is low. Strong tradeoffs can prevent local adaptation in spatially variable environments because selection favors habitat specialists that track a specific habitat regardless of its frequency in the environment (Levins, 1968). For example, a riparian specialist may experience similar selection in rivers of high rainfall regions and deserts, even though the habitat is much rarer in the latter. In *E. cardinalis* we found substantial genetically based variation among populations along a phenotypic axis from fast to slow growth that varied over a large spatial scale (Fig. 3). If this variation is adaptive, it suggests one of several possibilities to investigate in the future: the fitness tradeoff between low versus high latitude environments is not too strong nor swamped by demographic asymmetry or maladaptive gene flow. That is, alleles favoured at one latitude are not strongly selected against when they flow to another population, allowing locally adaptive genetic variation to be maintained by spatially heterogeneous selection. We also know from previous work that population size does not vary strongly with latitude (Angert, unpub. data). Gene flow appears to be high, but attenuates at broad spatial scales, especially between Southern ( $< 35^\circ\text{N}$ ) and Northern portions of the range (Paul et al., In review).

Nevertheless, local gene flow from similar environments may shape how selection varies with latitude. Theory predicts that populations will not be perfectly adapted to their

386 immediate habitat when there is gene flow from surrounding populations with different  
387 optima (Lenormand, 2002). With spatial heterogeneity and gene flow, traits will not covary  
388 perfectly with the local optimum (Slatkin, 1978; Paul et al., 2011; Hadfield, 2016), but  
389 should instead better match the average environment experienced by nearby populations  
390 connected through gene flow, which we refer to as the climatic neighborhood. Gene flow  
391 and spatial heterogeneity may therefore be important in maintaining genetic variation  
392 (Yeaman and Jarvis, 2006). As this hypothesis predicts, climatic neighborhoods (62-km  
393 buffer around populations) correlated with traits and latitude of occurrences better than  
394 local climate (Fig. 4). We interpret this as suggestive evidence that gene flow between  
395 neighboring *E. cardinalis* populations shapes selection – populations are locally adapted to  
396 prevailing climate in their neighborhood, but perhaps not perfectly adapted to their local  
397 climate. This may not greatly constrain local adaptation because local and neighborhood  
398 climate values were generally similar in *E. cardinalis* populations (Fig. 5), at least at the  
399 resolution of ClimateWNA (90 m<sup>2</sup>). Therefore, we would predict in reciprocal transplants  
400 that populations whose local climate is farther from their neighborhood average would be  
401 less well adapted than those close to their neighborhood average.

402 It is reasonable to predict that southern populations, which appear to experience more  
403 frequent drought years (see below), might have physiological adaptation to survive and  
404 grow in drier soil. We found no evidence for this type of drought tolerance; all popula-  
405 tions responded to drought and temperature similarly (Table 3). Plants grew faster in  
406 the Hot treatment, but there was little effect of drought on growth. Rather, the effects  
407 of drought took longer to materialize but resulted in high mortality, especially in the Hot  
408 treatment. However, there was no differential mortality among populations in this treat-  
409 ment. Although our results indicate that this axis of the species niche may be constrained,  
410 plants have multiple ways to resist drought through both tolerance and escape (Ludlow,  
411 1989; Kooyers, 2015). Next, we consider why drought tolerance may be less important in local  
412 adaptation than a form of escape for this species.

413 We hypothesize that tolerance to dry soil may be constrained by a combination of strong  
414 fitness tradeoffs, demographic asymmetry, and gene flow. Soil moisture in riparian habitats  
415 where *E. cardinalis* lives is highly heterogeneous at very small spatial scales (several me-  
416 ters). Plants in the stream never have to tolerate drought whereas plants only a few meters  
417 away may experience extreme drought since there is little direct precipitation during the  
418 growing season in Mediterranean climates of western North America. We hypothesize alle-  
419 les that confer greater drought tolerance may be quite costly in well-watered soils, and *vice*  
420 *versa*, leading to strong fitness tradeoffs. Such tradeoffs would promote specialization to  
421 one soil moisture or another, thereby inhibiting the evolution of broad environmental tol-  
422 erance within a population. Demography and gene flow may reinforce niche conservatism.  
423 A new mutant with increased drought tolerance that could survive at the resource-poor  
424 margin of a population would likely be demographically overwhelmed by the larger census  
425 populations that can be maintained in higher-resource environments. Infrequent wet years  
426 may also produce most seeds, so selection is weighted towards alleles that have high fitness  
427 in the wet environment, even if dry years are more frequent (Templeton and Levin, 1979;  
428 Brown and Venable, 1986). Finally, gene flow, which is generally high among *E. cardinalis*  
429 populations within the same ecoregion (Paul et al., In review), will thwart local adapta-  
430 tion and reinforce specialization. Thus, the spatial grain of the environment, demographic  
431 asymmetry, and gene flow may conspire to constrain local adaptation along this environ-  
432 mental axis. Consistent with this hypothesis, recent record-setting droughts have caused  
433 the decline or even local extinction of some natural populations of *E. cardinalis* (Sheth and  
434 Angert, 2017).

435 In sum, these results indicate that intrinsic differences in physiology and growth, but not  
436 plastic responses to temperature and drought, mediate local adaptation to climate in *E.*  
437 *cardinalis*. Next, we would like to understand why variation in these particular traits  
438 may be adaptive. We argue that temporally more variable environments, as experienced  
439 by southern populations, select for a more ‘annualized’ life-history strategy, a form of

drought escape. Demographic observations in natural populations of *E. cardinalis* reveal that southern populations tend to flower earlier at a smaller size, while northern populations invest more in vegetative growth (Sheth and Angert, 2017). The association between position along the ‘fast-slow’ continuum and associated traits in *E. cardinalis* is similar to interspecific relationships between growth, functional traits, and life history (Adler et al., 2014; Salguero-Gómez et al., 2016). However, we cannot exclude unexplored factors (e.g. edaphic conditions, competitors, pollinators, etc.) which may also contribute to the latitudinal cline.

Greater investment in aboveground growth, as opposed to belowground storage for future seasons, may be favoured in climates with more frequent drought years, but maladaptive in climates with more consistent precipitation. This is a form of drought escape in that plants are investing more reproduction in the present to avoid possible drought in subsequent years. Suppose plants that grow quickly and allocate new resources to continued growth rather than storage have higher fitness over a single growing season. However, by not allocating resources to storage, these fast-growing plants begin future seasons at a deficit. Therefore, in a stable environment where winter survivorship is assured in most years, failure to store resources may reduce lifetime fitness. But for perennial herbs in Mediterranean climates, a dry winter (rainy season) can kill the rhizomes (underground stems that store nutrients for future growth) before emergence or aboveground stems before flowering. If drought years occur frequently enough, selection may favour the fast-growing strategy because there is no advantage to storage if drought kills plants before flowering. Considering life-history strategy as a continuum from no storage (annual) to lots of storage (perennial), we hypothesize that the optimal allocation to aboveground growth is more ‘annualized’ in southern climates that have greater interannual variation in precipitation. This scenario differs from classic drought escape syndromes in which plants speed up development early in the season before the onset of drought.

The hypothesis that greater precipitation variability selects for an annualized life history

467 is tentative, but consistent with theory and data from other species. Life history theory  
 468 shows that less variable environments are one factor that favours the evolution of perenni-  
 469 ality (Stearns, 1976; Iwasa and Cohen, 1989; Friedman and Rubin, 2015). Populations of  
 470 the perennial *Plantago asiatica* show a similar latitudinal cline in growth and allocation to  
 471 storage (Sawada et al., 1994), though these authors attribute the cline to variation in grow-  
 472 ing season length. There are also life history clines in the closely related species *E. guttata*,  
 473 but the underlying traits and climatic drivers are quite different. Annual *E. guttata* flower  
 474 sooner and produce fewer stolons in response to climates with shorter seasons and more  
 475 intense summer drought (Lowry and Willis, 2010; Friedman et al., 2015; Kooyers et al.,  
 476 2015). In contrast, there are no truly annual (monocarpic and semelparous) populations of  
 477 *E. cardinalis*. Rather, our hypothesis states that climatic variability selects on quantitative  
 478 variation in allocation to growth versus storage. This hypothesis makes several indepen-  
 479 dent, testable predictions. The allocation tradeoff predicts that northern populations will  
 480 provision more photosynthetic assimilate to rhizomes compared with southern populations.  
 481 If southern populations are indeed more ‘annualized’ because more frequent droughts cause  
 482 mortality, then we predict that species distribution models using recent climate would best  
 483 predict occurrences in the south, whereas longer term climate would be a better predictor  
 484 in the north. Finally, we predict that southern populations would show greater variation  
 485 in the size of recruits and higher maximum population growth rates.

486 In summary, we found evidence for a coordinated latitudinal cline in germination rate,  
 487 photosynthesis, and growth, suggesting local adaptation. We therefore predict to find  
 488 different optima for these traits in different climates. We did not find evidence that the  
 489 relative performance of populations shifts with temperature or watering regime, suggesting  
 490 relatively little variation in plasticity. Exploratory analysis implicate that more variable  
 491 precipitation regimes at lower latitude drive much of the latitudinal cline, though other  
 492 climatic factors could also contribute. Interestingly, the climatic neighborhood may shape  
 493 selective pressures more than local climate. In the future, we will use field experiments to

test whether greater variation in precipitation selects for faster growth and if selection on temperature/drought responses does not vary among populations. By doing so, we aim to understand why certain physiological and developmental mechanisms, but not others, contribute to local adaptation.

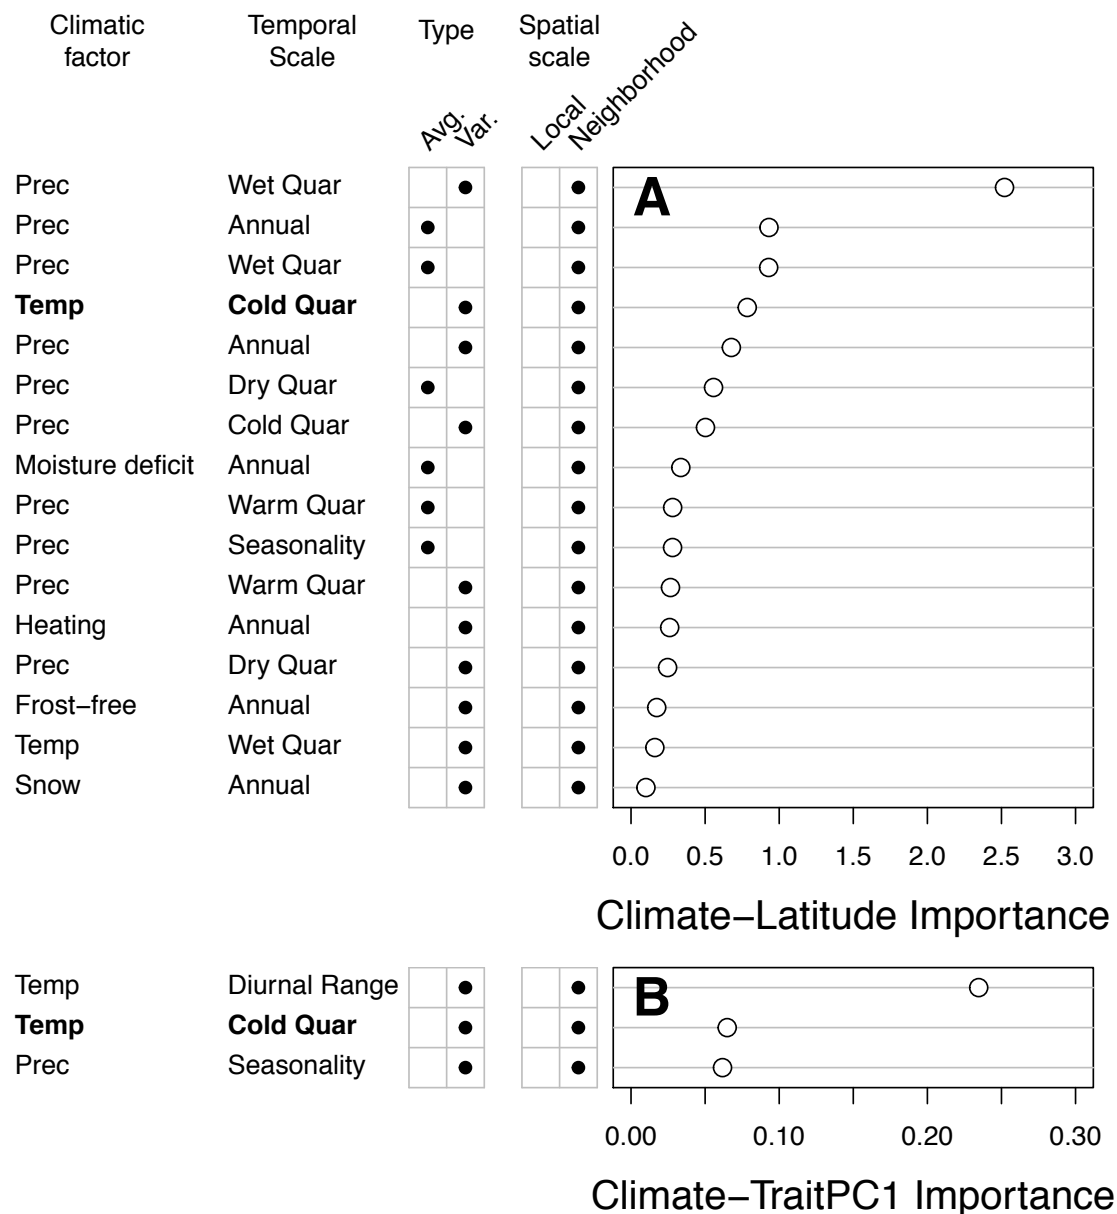

**Figure 2:** Overview of method for identifying putative climatic selective agents underlying latitudinal cline. We looked for climate variables that explained both the latitude of 356 *E. cardinalis* occurrences ('Climate-Latitude variables') and with traits ('Climate-Trait variables'). For Climate-Latitude variables we extracted climate data from recent occurrences located throughout California and Oregon, USA (shown in map). For Climate-Trait variables, we extracted climatic data for the 16 focal populations. For both analyses, we extracted local and neighborhood climate. Local climate refers to climate only from where a population was collected ( $x_{i,0}$ ). Neighborhood climate was calculated as the average over 1000 points in a 62-km radius climatic neighborhood ( $x_{i,1}, x_{i,2}, \dots$ ), but only along stream habitats as *E. cardinalis* is riparian. We identified climatic factors that most strongly predicted latitude of occurrences (Climate-Latitude variables) and traits (Climate-Trait variables), as shown for hypothetical data in plots at the bottom of the figure.

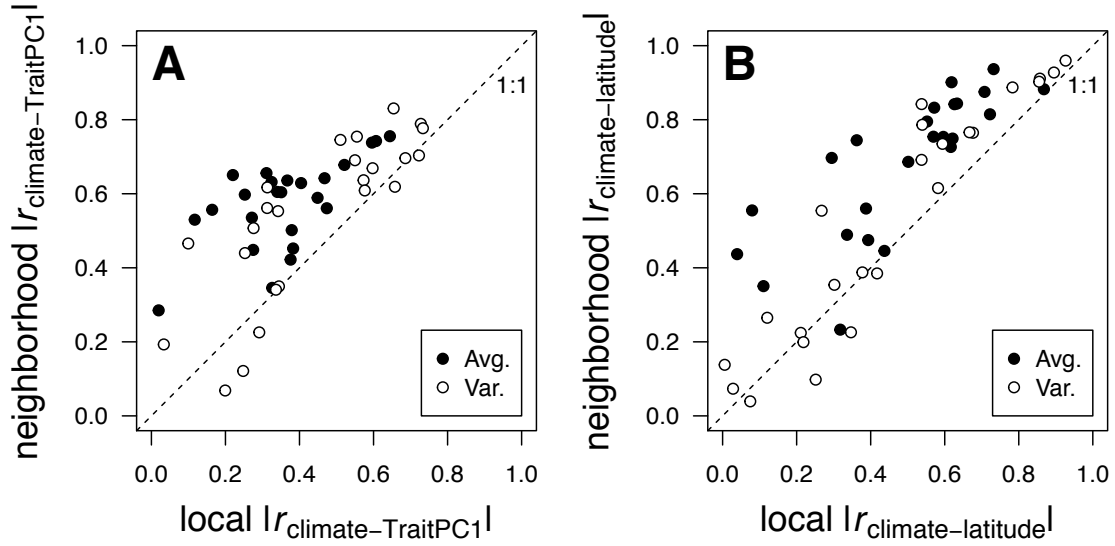

**Figure 3:** Trait variation, from fast to slow growth, is closely associated with latitude. Each point is a population's latitude of origin (x-axis) and position along the slow to fast growth axis (y-axis), defined as Principal Component 1 of four traits (see Material and Methods). The line and 95% confidence intervals were estimated using linear regression.

**Figure 4:** Climatic variation integrated over climatic neighborhood is closely correlated with latitude of *E. cardinalis* and trait variation. A. Using Random Forest regression, we identified 16 climatic variables significantly (high importance) associated with latitude of *E. cardinalis* occurrences. B. Only one of the most important Climate-Latitude variables (in bold) was among the most important Climate-TraitPC1 variables. Variable importance is defined as the average amount a climate variable reduces mean-squared error in the predicted response (TraitPC1 or Latitude), compared to a randomly permuted dataset, across all trees in the random forest (see Genuer et al. [2015] for further detail). Note that the Importance values in A and B are not comparable because the dependent variables (Latitude and Trait PC1, respectively) are on different scales. Climatic variables (left of A; right of B) are defined by four qualities: Climatic factor – Temperature (Temp), Precipitation (Prec), Heating degree-days (Heating), Snow (precipitation as snow); Temporal scale – Annual, Coldest quarter (Cold Quar), Warmest Quarter (Warm Quar), Wettest quarter (Wet Quar), Driest Quarter (Dry Quar), or Seasonality; Type – 30-year average (Avg.) or coefficient of variation (Var.); Spatial scale – local or 62-km radius climatic neighborhood.

**Figure 5:** Neighborhood climate predicts TraitPC1 ('Climate-trait', panel A) and Latitude of occurrences ('Climate-latitude', panel B) better than local climate. Each point is the absolute value of the Pearson correlation coefficient ( $|r|$ ) between TraitPC1 (A) or latitude (B) for 24 climatic factors, for which we used both the 30-year mean (closed circles) and coefficient of variation (open circles). Most points lie above the 1:1 line, indicating stronger correlations with neighborhood compared to local climate. Neighborhood climate was integrated over a 62-km radius around focal populations (see text for further detail).

**Figure 6:** Variation in precipitation is correlated with TraitPC1 and latitude. A. Greater values of TraitPC1 are associated with greater interannual variation in precipitation of the wettest quarter. This was the most important Climate-Latitude variable, but not among the most important Climate-TraitPC1 variables. B. However, a closely related parameter, interannual variation in precipitation seasonality, was among the most important Climate-TraitPC1 variables. C. Across focal populations, variation in precipitation of the wettest quarter and seasonality are closely correlated. D. Southern populations of *E. cardinalis* experience much greater interannual variation in precipitation. In all panels, we report climatic neighborhood values (see Material and Methods). Regression lines, 95% confidence intervals, and coefficients of determination ( $R^2$ ) were calculated using linear regression.

678 **Supporting Information**

679 **Supporting Tables**

**Table S1:** Initial size of seedlings did not vary among Populations, Families, or Treatments. We used a censored Gaussian model of initial size at the outset of the experiment (longest leaf length of the first true leaves). The model was censored because we could not accurately measure leaves less than 0.25 mm with digital callipers (217 of 702, 30.9%, were too small). We fit models using a Bayesian MCMC method implemented using the MCMCglmm function with default priors in the R package **MCMCglmm** version 2.17 (Hadfield, 2010). We estimated the posterior distribution from 1000 samples of an MCMC chain run for  $10^5$  steps after a  $10^4$  step burn-in. We used step-wise backward elimination procedure to find the best-supported model according to Deviance Information Criterion (DIC).

**Table S2:** Climatic variables used

Abbreviation	Climate variable
DD_0	degree-days below 0°C(chilling degree-days)
DD5	degree-days above 5°C(growing degree-days)
DD_18	degree-days below 18°C(heating degree-days)
DD18	degree-days above 18°C(cooling degree-days)
NFFD	number of frost-free days
PAS	precipitation as snow (mm) between August in previous year and July in current
Eref	Hargreaves reference evaporation (mm)
CMD	Hargreaves climatic moisture deficit (mm)
RH	mean annual relative humidity
bio1	annual mean temperature
bio2	mean diurnal range (mean of monthly (max temp - min temp))
bio3	isothermality (bio2/bio7) (* 100)
bio4	temperature seasonality (standard deviation *100)
bio5	max temperature of warmest month
bio6	min temperature of coldest month
bio7	temperature annual range (bio5-bio6)
bio8	mean temperature of wettest quarter
bio9	mean temperature of driest quarter
bio10	mean temperature of warmest quarter
bio11	mean temperature of coldest quarter
bio12	annual precipitation
bio15	precipitation seasonality (coefficient of variation)
bio16	precipitation of wettest quarter
bio17	precipitation of driest quarter
bio18	precipitation of warmest quarter
bio19	precipitation of coldest quarter

**Table S3:** Analysis of variance (ANOVA) table on leaf expansion rate (LER) using **lmerTest** (Kuznetsova et al., 2016). Family and Block were included as random effects. Abbreviations: SS = sum of squares; MS = mean sum of squares (SS / df1); df1 = numerator degrees of freedom; df2 = denominator degrees of freedom.

	SS	MS	df1	df2	<i>F-value</i>	<i>P-value</i>

Population $\times$ Temperature $\times$ Water	0.2	15	1.000

**Table S7:** Important climatic variables predicting latitude of *E. cardinalis* populations ('Climate-Latitude') and the first principal component of traits measured in a common garden ('Climate-TraitPC1'). Local climatic variables were measured from the exact location of collection; neighborhood climatic variables were averaged from a 62-km neighborhood around population (see Material and Methods). Importance and significance were determined using the variable selection using random forests (VSURF) algorithm (see Material and Methods). Climatic variables are described in Table S2.  $\mu$  signifies the mean of the climate variables from 1981–2010;  $\sigma$  indicates coefficient of variation among years.

Climate-Latitude variables	Climate-TraitPC1 variables
Precipitation of wettest quarter ( $\sigma$ , neighborhood)	Mean diurnal range ( $\sigma$ , neighborhood)
Annual precipitation ( $\mu$ , neighborhood)	Mean temperature of coldest quarter ( $\sigma$ , neighborhood)
Precipitation of wettest quarter ( $\mu$ , neighborhood)	Precipitation seasonality ( $\sigma$ , neighborhood)
Mean temperature of coldest quarter ( $\sigma$ , neighborhood)	
Annual precipitation ( $\sigma$ , neighborhood)	
Precipitation of driest quarter ( $\mu$ , neighborhood)	
Precipitation of coldest quarter ( $\sigma$ , neighborhood)	
Hargreaves climatic moisture deficit ( $\mu$ , neighborhood)	
Precipitation of warmest quarter ( $\mu$ , neighborhood)	
Precipitation seasonality ( $\mu$ , neighborhood)	
Precipitation of warmest quarter ( $\sigma$ , neighborhood)	
Heating degree-days ( $\sigma$ , neighborhood)	
Precipitation of driest quarter ( $\sigma$ , neighborhood)	
Number of frost-free days ( $\sigma$ , neighborhood)	
Mean temperature of wettest quarter ( $\sigma$ , neighborhood)	
Precipitation as snow ( $\sigma$ , neighborhood)	

**Figure S1:** Southern populations germinate faster. Each point is a population of *E. cardinalis* showing its latitude of origin (x-axis) and model-predicted days to germination in days under growth chamber conditions (see Material and Methods). Bars around each point are 95% confidence intervals. Predicted time to germination and confidence intervals are based on survival regression (see Materials and Materials). The line is the linear regression of  $\log(\text{model-predicted days to germination}) \sim \text{latitude}$ . The  $P$ -value of the regression is given in the upper left corner.

**Figure S2:** Southern populations grow faster. Each point is a population of *E. cardinalis* showing its latitude of origin (x-axis) and model-predicted leaf expansion rate during the rosette phase. Bars around each point are 95% confidence intervals. Predicted leaf expansion rate based least-square mean estimates and confidence intervals were calculated from linear mixed-effects models (see Materials and Materials). The line is the linear regression of model-predicated leaf expansion rate  $\sim$  latitude. The  $P$ -value of the regression is given in the upper right corner.

**Figure S3:** Southern populations grow faster. Each point is a population of *E. cardinalis* showing its latitude of origin (x-axis) and model-predicted stem elongation rate. Bars around each point are 95% confidence intervals. Predicted stem elongation rate based least-square mean estimates and confidence intervals were calculated from linear mixed-effects models (see Materials and Materials). The line is the linear regression of model-predicated stem elongation rate  $\sim$  latitude. The  $P$ -value of the regression is given in the upper right corner.

**Figure S4:** Southern populations photosynthesize faster. Each point is a population of *E. cardinalis* showing its latitude of origin (x-axis) and model-predicted instantaneous photosynthetic rate. Bars around each point are 95% confidence intervals. Predicted photosynthetic rates based least-square mean estimates and confidence intervals were calculated from linear mixed-effects models (see Materials and Materials). The line is the linear regression of model-predicted photosynthetic rate  $\sim$  latitude. The *P*-value of the regression is given in the upper right corner.

**Figure S5:** Reaction norms signify little Population  $\times$  Treatment interactions. For all panels, black lines represent population-level reaction norms from Wet to Dry in the Cool temperature treatment (dashed black lines) and Hot temperature treatment (solid black lines); gray lines represent reaction norms from Cool to Hot in the Wet treatment (solid gray lines) and Dry treatment (dashed gray lines). The responses shown are (A) leaf expansion rate, (B) stem elongation rate, (C) photosynthesis, and (D) survivorship (= 1 - mortality).

**Figure S6:** Trait variation, from fast to slow growth, is closely associated with neighborhood variation in temperature of the coldest quarter ( $\text{bio11}_\sigma$ ). Each point is a population coefficient of variation in  $\text{bio11}$  averaged over a 62-km climatic neighborhood (x-axis) and position along the slow to fast growth axis (y-axis), defined as Principal Component 1 of four traits (see Material and Methods). The line and 95% confidence intervals were estimated using linear regression.

## 681 Supporting Material and Methods

### 682 Temperature treatments

683 We simulated typical growing season (June 1 - August 15) air temperatures at the two most  
684 thermally divergent focal sites in our study, Whitewater Canyon (WWC, Hot) and Little  
685 Jameson (LIJ, Cool). We downloaded daily interpolated mean, minimum, and maximum  
686 air temperature from 13 years (2000-2012) at both sites from ClimateWNA (Wang et al.,  
687 2012). This range was chosen because seeds used in the experiment were collected around  
688 2012, thus their presence in that location at that time suggests that populations were able  
689 to persist there for at least some years before collection. Monthly temperatures from Cli-  
690 mateWNA are highly correlated with the air temperature recorded from data loggers in  
691 the field at these sites (A. Angert, unpub. data). Hence, the ClimateWNA temperature  
692 profiles are similar to actual thermal regimes experienced by *E. cardinalis* in nature. We  
693 simulated realistic temperature regimes by calculating the mean temperature trend from  
694 June to August using LOESS (Cleveland et al., 1992). The residuals were highly autocor-  
695 related at both sites (warmer than average days are typically followed by more warm days)  
696 and there was strong correlation ( $r = 0.65$ ) between sites (warm days in WWC were also  
697 warm in LIJ). The ‘VARselect’ function in the **vars** package for R (Pfaff, 2008) indicated  
698 that a lag two Vector Autoregression (VAR(2)) model best captured the within-site auto-  
699 correlation as well as between-site correlation in residuals. We fit and simulated from the  
700 VAR(2) model using the package **dse** (Gilbert, 2014) in R. Simulated data closely resem-  
701 bled the autocorrelation and between-site correlation of the actual data. From simulated  
702 mean temperature, we next selected minimum and maximum daily temperatures. Mean,  
703 min, and max temperature were highly correlated at both sites. We chose min and max  
704 temperatures using site-specific fitted linear models between mean, max, and min tem-  
705 perature, with additional variation given by normally distributed random deviates with  
706 variance equal to the residual variance of the linear models. For each day, the nighttime

707 (22:00 - 6:00) chamber temperature was set to the simulated minimum temperature. Dur-  
708 ing the middle of the day, temperature was set to the simulated maximum temperature,  
709 with a variable period of transition between min and max so that the average temperature  
710 was equal the simulated mean temperature.

## 711 **Watering treatments**

712 For watering treatments, we simulated two extreme types of streams where *E. cardinalis*  
713 grows. In the well-watered treatment, we simulated a large stream that never goes dry  
714 during the summer growing season. In the drought treatment, we simulated a small stream  
715 that has ample flow at the beginning of the season due to rain and snow melt, but gradually  
716 dries down through the summer. In both treatments, plants were bottom-watered using  
717 water chilled to 7.5°C. Plants in the well-watered treatment were fully saturated every two  
718 hours during the day. Watering in the drought treatment gradually declined from every  
719 two hours to every day between May 20 (36 days after sowing) and 10 June (57 days after  
720 sowing). Simultaneously, the amount of bottom-watering per flood decreased, such that  
721 only the bottom of the cone-tainers were wetted by the end of the experiment.
